## Introduction

Stellar winds in general ism planets

Empirical studies are vital to constrain physical parameters of the mass loss process.

## 1.1 Motivation for Researching Cool Evolved Stellar Outflows

Mass loss from non-coronal spectral-type K through mid-M evolved stars plays a crucial role in galactic evolution and ultimately provides part of the material required for the next generation of stars and planets. This mass loss occurs via a cool ( $T_e \lesssim 10^4 K$ ) wind with terminal velocities typically less than the photospheric escape velocity ( $10 \leq v_\infty \leq 50 \text{ km s}^{-1}$ ). The mass loss rates for the red giants are significant, typically  $10^{-9} - 10^{-11} M_\odot \text{ yr}^{-1}$ , and are even higher for the more short-lived red supergiants, typically  $10^{-4} - 10^{-6} M_\odot \text{ yr}^{-1}$ . This implies that a substantial fraction of the star's initial mass can be dispersed to the Interstellar Medium (ISM) during its post main sequence lifetime. Mass loss from these stars is therefore a crucial factor governing stellar evolution and also in explaining the frequency of supernovae in the galaxy (Harper, 1996). Despite the importance of this phenomenon and decades of study, the mechanisms that drive winds from evolved spectral-type K through mid-M stars remain unclear [clearly laid out by Holzer & MacGregor (1985) but still unsolved, e.g., Crowley *et al.* (2009)]. There is insufficient atomic, molecular, or dust opacity to drive a radiation-driven outflow (Jones, 2008; Zuckerman *et al.*, 1995) and acoustic/pulsation models cannot drive the observed mass loss rates (Sutmann & Cuntz, 1995). Ultraviolet (UV) and optical observations reveal an absence of significant hot wind plasma and the winds are thus too cool to be Parker-type thermally-driven flows (e.g., Ayres *et al.*, 1981; Haisch *et al.*, 1980; Linsky & Haisch, 1979).

An important discovery in late-type evolved stellar atmospheres resulted from the first ultraviolet survey of such stars using the International Ultraviolet Explorer (IUE). The survey revealed a 'transition region dividing line' in the giant branch near spectral type K1 III which separates these stars based on the properties of their atmospheres (Linsky & Haisch, 1979). Stars blueward of the dividing line were found to possess chromospheres and transition regions like the Sun, while stars on the red side were found to possess chromospheres and cool winds. X-ray observations showed that this dividing line extended to coronal emission (Ayres *et al.*, 1981). Around the same time, another class of late-type evolved star emerged which showed signs of possessing both a transition region and a cool

wind (e.g., Reimers, 1982). Many of these so-called ‘hybrid atmosphere’ stars now also show evidence for coronal emission, albeit much weaker than on the blue side of the dividing line (Ayres *et al.*, 1997; Dupree *et al.*, 2005). Understanding the nature of the atmospheric structure of the late-type evolved stars will ultimately lead to a broader understanding of the mass-loss process for these stars.

Magnetic fields are most likely involved in the mass loss process, although current magnetic models are also unable to explain spectral diagnostics. Exquisite high signal-to-noise (S/N) ratio *Hubble Space Telescope* (HST) UV spectra have revealed that the 1-D linear Alfvén wave-driven wind models of the 1980s (e.g., Harper 1988; Hartmann & MacGregor 1980) are untenable (Harper *et al.*, 2001). These models predict chromospheres as integral parts of a turbulent, extended and heated wind acceleration zone, but the theoretical line profiles and electron densities do not agree with the HST spectra, (e.g., Judge & Carpenter, 1998). One important property of cool evolved star winds gleaned from UV spectra is that, for the most part, the red giant winds accelerate in a quasi-steady manner and are not the result of ballistic ejecta as shown by the increase of wind scattering absorption velocity with optical depth in Fe II lines (Carpenter *et al.*, 1999). A new generation of theoretical models with outflows driven within diverging magnetic flux tubes have now emerged (Falceta-Gonçalves *et al.*, 2006; Suzuki, 2007) but these too are not yet in agreement with observations (Crowley *et al.*, 2009). Progress in this field continues to be driven by observations which can test existing models and theories, and provide new insights and constraints into the mass loss problem.

## 1.7 Radio Observations of Stellar Atmospheres

In the following sections we present the basic definitions used to describe radio observations of stellar atmospheres. We define the *brightness temperature* which is commonly used in radio astronomy to measure the brightness of a source, along with its relationship to the fundamental quantity measured by a radio telescope, the *flux density*. Focusing on thermal emission, we describe how the flux density varies with frequency when observing both optically thin and optically thick stellar atmospheres.

### 1.7.1 Brightness Temperature

In thermodynamic equilibrium the spectral distribution or brightness,  $B_\nu$ , of the radiation of a black body with temperature  $T_e$  is given by the Planck law

$$B_\nu(T_e) = \frac{2h\nu^3}{c^2} \frac{1}{e^{h\nu/kT_e} - 1} \quad (1.2)$$

and has units of flux per frequency interval per solid angle. One can easily switch to a wavelength scale using  $B_\nu d\nu = B_\lambda d\lambda$ . When  $h\nu \ll kT_e$  Equation 1.2 becomes the *Rayleigh-Jeans Law*

$$B_\nu(T_e) = I_\nu(T_e) = \frac{2\nu^2 kT_e}{c^2}. \quad (1.3)$$

This equation does not contain Planck's constant and therefore is the classical limit of the Planck Law. We have also included the specific intensity,  $I_\nu$ , here as it has the same units as the spectral brightness and for blackbody radiation,  $I_\nu(T_e) = B_\nu(T_e)$ . This equation is valid for all thermal radio sources except in the millimeter or sub-millimeter regime at low temperatures (Rohlfs & Wilson, 1996). In the Rayleigh-Jeans relation, the brightness is strictly proportional to the thermodynamic temperature of the black body. In radio astronomy it is customary to measure the brightness of an object by its *brightness temperature*,  $T_b$ . Therefore, the brightness temperature is the temperature at which a blackbody would have to be in order to reproduce the observed brightness of an object at frequency  $\nu$  and is defined as

$$T_b = \frac{c^2}{2k\nu^2} I_\nu. \quad (1.4)$$

If  $h\nu/kT \ll 1$  and if  $I_\nu$  is emitted by a blackbody, then  $T_b$  is the thermodynamic temperature of the source. If other processes are responsible for the emission or if the frequency is so high that Equation 1.3 is not valid, then  $T_b$  is different from the thermodynamic temperature of a black body.

The equation of radiative transfer describes the change in specific intensity of a ray along the line of sight in a slab of material of thickness  $ds$

$$\frac{dI_\nu}{ds} = \varepsilon_\nu - \kappa_\nu I_\nu, \quad (1.5)$$

## 1.7 Radio Observations of Stellar Atmospheres

---

where  $\varepsilon_\nu$  and  $\kappa_\nu$  are the emissivity (in  $\text{erg s}^{-1} \text{cm}^{-3} \text{Hz}^{-1} \text{sr}^{-1}$ ) and the absorption/opacity coefficient (in  $\text{cm}^{-1}$ ) of the plasma. In thermodynamic equilibrium the radiation is in complete equilibrium with its surroundings and the brightness distribution is described by the Planck function

$$\frac{dI_\nu}{ds} = 0, \quad I_\nu = \frac{\varepsilon_\nu}{\kappa_\nu} = B_\nu(T_e). \quad (1.6)$$

Equation 1.5 can be solved by first defining the optical depth,  $d\tau_\nu$ , as

$$d\tau_\nu = -\kappa_\nu ds, \quad (1.7)$$

and then integrated by parts between 0 to  $s$ , and  $\tau$  to 0, to give

$$I(s) = I(0)e^{-\tau(s)} + \int_{\tau(s)}^0 e^{-\tau} \frac{\varepsilon_\nu}{\kappa_\nu} d\tau. \quad (1.8)$$

The second term within the integral is known as the source function,  $S_\nu$ , and this can be taken outside of the integral in the case of a homogeneous source, i.e., one for which both the emissivity and absorption coefficient are constant along the ray path. The solution then to the equation of radiative transfer for a homogeneous source is

$$I_\nu = I_0 e^{-\tau} + \frac{\varepsilon_\nu}{\kappa_\nu} (1 - e^{-\tau}). \quad (1.9)$$

Using Equations 1.4 and 1.6 one obtains

$$T_b = T_0 e^{-\tau} + T_e (1 - e^{-\tau}). \quad (1.10)$$

This equation assumes thermodynamic equilibrium and so only holds for a thermal source. If  $T_e$  is replaced with  $T_{\text{eff}} = h\nu/k$  then this equation becomes valid for a homogeneous nonthermal source, i.e.,

$$T_b = T_0 e^{-\tau} + T_{\text{eff}} (1 - e^{-\tau}). \quad (1.11)$$

For an isolated thermal source, there are two limiting cases:

$$T_b = T_e \quad (\text{i.e., for optically thick } \tau \gg 1) \quad (1.12)$$

## 1.7 Radio Observations of Stellar Atmospheres

---

and

$$T_b = \tau T_e \quad (\text{i.e., for optically thin } \tau \ll 1). \quad (1.13)$$

In these equations,  $T_e$  can also be replaced by  $T_{\text{eff}}$  if the radio emission is non-thermal. Also, these equations are only valid if the source is spatially resolved. If the source is unresolved then an upper limit to  $T_e/T_{\text{eff}}$  is found.

### 1.7.2 Brightness Temperature and Flux Density

The flux density,  $F_\nu$ , is a fundamental quantity measured by a radio telescope and is usually measured in Janskys (Jy) where  $1 \text{ Jy} = 1 \times 10^{-26} \text{ W m}^{-2} \text{ Hz}^{-1}$ . The observed flux density measured by the radio telescope is

$$F_\nu = \int_{\Omega} I_\nu d\Omega \quad (1.14)$$

where  $\Omega$  is the solid angle subtended by the star. The radio emission from evolved cool stars is almost purely thermal and so Equation 1.14 becomes

$$F_\nu = \frac{\pi R_\star^2}{d^2} \frac{2k\nu^2 T_b}{c^2}. \quad (1.15)$$

The angular diameter of a star in radians is  $\phi_\star = 2R_\star/d$  and so

$$F_\nu = \frac{\pi k \phi_\star^2 T_b}{2\lambda^2} \quad (1.16)$$

If  $\phi_\star$  has major and minor axes  $\phi_{\text{maj}}$  and  $\phi_{\text{min}}$  then

$$T_b(K) = 1.96 F_\nu(\text{mJy}) \left( \frac{\lambda}{\text{cm}} \right)^2 \left( \frac{\phi_{\text{min}}}{\text{arcsec}} \frac{\phi_{\text{min}}}{\text{arcsec}} \right)^{-1}. \quad (1.17)$$

Therefore, if an optically thick stellar atmosphere can be spatially resolved (i.e.,  $\phi_{\text{maj}}$  and  $\phi_{\text{min}}$  can be measured) then the flux density at a particular wavelength tells gives the brightness temperature and therefore the electron temperature. Unfortunately, the number of stars that can have their atmospheres spatially resolved at radio wavelengths is low due to their relatively small angular diameters. However, different layers of stellar atmospheres can still be probed due to the nature of the free-free radio opacity which is discussed in the next section.

### 1.7.3 Thermal Free-free Radio Opacity

In Section 1.6.1 we derived an expression for the thermal free-free emissivity of an ionized gas. Since we assumed LTE at some temperature  $T$ , we can use Kirchoff's law to find the thermal radio free-free opacity (absorption coefficient):

$$\kappa_\nu^{ff} = \frac{\epsilon_\nu^{ff} c^2}{2kT_e \nu^2} \quad (1.18)$$

Substituting in Equation ?? then gives a value for the radio opacity which is corrected for stimulated emission

$$\kappa_\nu^{ff} = \frac{0.018 Z^2 n_e n_i g_{ff}(\nu, T_e)}{T_e^{1.5} \nu^2} \quad (1.19)$$

The Gaunt factor is slightly dependent on temperature and frequency and at cm-wavelengths is given by

$$g_{ff}^{cm} = 11.96 T_e^{0.15} \nu^{-0.1} \quad (1.20)$$

(Altenhoff *et al.*, 1960), while in the sub-millimeter regime it is slightly different

$$g_{ff}^{sub-mm} = 24.10 T_e^{0.26} \nu^{-0.17} \quad (1.21)$$

(Hummer, 1988). The abundant species in the atmospheres of cool evolved stars are either neutral or single ionized so that  $Z = 1$  and  $n_e = n_i$ . Focusing on centimeter wavelengths, the radio opacity is then

$$\kappa_\nu^{ff} = \frac{0.212 n_e^2}{T_e^{1.35} \nu^{2.1}} \quad \text{cm}^{-1}. \quad (1.22)$$

Therefore, the free-free opacity increases towards lower frequencies as  $\kappa_\nu^{ff} \propto \nu^{-2.1}$  (or longer wavelengths as  $\kappa_\lambda^{ff} \propto \lambda^{2.1}$ ). This means that the optical depth,  $\tau_\lambda = \int \kappa_\lambda dr$ , also increases towards longer wavelengths implying that the effective radius (i.e., the radius where  $\tau_\lambda = \tau_{\text{radial}}$ ) will increase with longer wavelengths. As a result, different layers of unresolved stellar atmospheres can be probed by observing them at different radio wavelengths.

In LTE, the solution to the equation of radiative transfer (i.e, Equation 1.9)

## 1.7 Radio Observations of Stellar Atmospheres

---

for a plasma with no background source can be written as

$$I_\nu = B_\nu(1 - e^{-\tau}). \quad (1.23)$$

An example of such a source is an isolated H II region. At long enough wavelengths the H II region becomes opaque so that  $\tau_\nu \gg 1$ . Equation 1.23 then tells us that the spectrum approaches that of a black body with a flux density varying as  $F_\nu \propto \nu^2$ . At short wavelengths where  $\tau_\nu \ll 1$ , the H II region is almost transparent, and the flux density becomes

$$F_\nu \propto \frac{2kT_e\nu^2}{c^2}\tau_\nu \propto \nu^{-0.1}. \quad (1.24)$$

These two scenarios are shown in Figure ?? along with the point where these two slopes intersect which corresponds to the frequency at which  $\tau \simeq 1$ . When the radio spectrum is plotted on a log-log plot as in Figure 1.2, the spectral slope is referred to as the spectral index,  $\alpha$ , and is defined:

$$\alpha = \frac{d \log F_\nu}{d \log \nu}. \quad (1.25)$$

### 1.7.4 Radio Excess from Stellar Outflows

Cool evolved stars have ionized or partially ionized outflows which emit an excess of continuum emission at long wavelengths. This flux excess is due to thermal free-free emission and is measured relative to the expected photospheric radio flux. If the atmosphere only consisted of a static homogeneous isothermal chromosphere then the radio spectrum would be the summation of the Rayleigh-Jeans tail of the Planck function from the photosphere and the H II spectrum discussed in the previous section. At long wavelengths then, this spectrum would again have a power law of slope  $F_\nu \propto \nu^2$ . Cool evolved stellar atmospheres cannot in general be described by this simple model because they possess stellar winds which are escaping the gravitational potential of the star. The atmospheric density thus varies with distance from the star. In this section we briefly outline a simple analytical model for the centimeter radio flux for a star with a isothermal, constant velocity and ionization fraction wind. In Chapter ?? we relax some of

**Figure 1.2:** The radio spectrum for a hypothetical H II region with no background illuminating source. At long wavelengths the source becomes opaque and has a black body like spectrum with  $\alpha = 2$ . At short wavelengths where  $\tau_\nu \ll 1$ , the H II region is almost transparent and  $\alpha = -0.1$ . Image adapted from NRAO’s *Essential Radio Astronomy* course.

these assumptions about the atmosphere’s properties to derive a more complete description of the centimeter radio spectrum for these stars.

To calculate the optical depth, we assume spherical geometry and integrate along a ray in the  $z$  direction with impact parameter  $b$ , as shown in Figure ???. The total optical depth at a frequency  $\nu$  is then

$$\tau_\nu = \int_{-\infty}^{\infty} \kappa_\nu dz \quad (1.26)$$

where the opacity is defined in Equation 1.22. For a constant velocity the electron

**Figure 1.3:** In spherical geometry the observer integrates along a ray path in the  $z$  direction, with impact parameter  $b$ , to calculate the total optical depth  $\tau_\nu$ , at a frequency  $\nu$ .

density is just  $n_e(r) = n_e(r_0)^2(r_0/r)^2$  and so the optical depth can be written as

$$\tau_\nu = \frac{0.212n_e(r_0)^2r_0^4}{T^{1.35}\nu^{2.1}} \int_{-\infty}^{\infty} \frac{dz}{(b^2 + z^2)^2} \quad (1.27)$$

The solution to this integral is given by

$$\int_{-\infty}^{\infty} \frac{dz}{(b^2 + z^2)^{A/2}} = b^{1-A} \sqrt{\pi} \frac{\Gamma(A/2 - 1/2)}{\Gamma(A/2)} \quad (1.28)$$

and so the total optical depth along a ray with impact parameter  $b$  is:

$$\tau_\nu = \frac{C}{b^3} \quad \text{where} \quad C = \frac{0.333n_e(r_0)^2r_0^4}{T^{1.35}\nu^{2.1}} \quad (1.29)$$

To calculate the flux density we use Equation 1.14 and assume that the source function is given by the Planck function in the Rayleigh-Jeans approximation:

$$F_\nu = \frac{2\pi}{d^2} \frac{2\nu^2 kT}{c^2} \int_0^\infty (1 - e^{-C/b^3}) b db \quad (1.30)$$

This integral can be solved using the following expression

$$\int_0^\infty y^{v-1}(1 - e^{-uy^p})dy = \frac{-1}{|p|}u^{-v/p}\Gamma\left(\frac{v}{p}\right), \quad (1.31)$$

which is given in [Gradshteyn & Ryzhik \(1994\)](#). The solution to our integral is then  $1.339C^{2/3}$  and so the total flux density can be written as

$$F_\nu = \frac{1.24 \times 10^{-16} n_e(r_0)^{4/3} r_0^{8/3} T^{0.1} \nu^{0.6}}{d^2} \quad \text{Jy.} \quad (1.32)$$

This equation shows that the expected spectral index for an isothermal constant velocity and ionization fraction stellar outflow (i.e., a constant property wind) is  $\alpha = 0.6$ .

The free-free emission from evolved cool stars is weak (usually less than 1 mJy at  $\lambda > 3$  cm) and therefore only a handful of these stars have known radio spectral indices at long wavelengths. The small number of such stars whose spectral indices are known have values which are greater than 0.6 (e.g. [Drake & Linsky, 1986](#)) due the assumptions in the constant property wind model being too simplistic. Betelgeuse is by far the best studied evolved cool star at radio wavelengths and its radio spectrum is shown in Figure 1.4 ([Newell & Hjellming, 1982](#)). Its spectral index clearly deviates from 0.6. In Chapter ?? we derive a new version of Equation 1.32 which accounts for a thermal gradient in the outflow along with flow acceleration. Nevertheless, Figure 1.4 is a good example of the radio flux excess which is present for all all cool evolved. Even though the observed flux density decreases to longer wavelengths, the excess increases relative to the expected photospheric flux as clearly seen in Figure 1.4.

## 1.8 Goals of this Thesis

**Figure 1.4:** Example of a cool evolved star’s radio flux excess, which is a direct result of their ionized atmospheres. Here, multi-wavelength radio observation of Betelgeuse are plotted along with a best fit power law indicating a spectral index of  $\alpha = 1.32$  (Newell & Hjellming, 1982). Even though the observed flux density decreases at longer wavelengths, the excess increases relative to the expected photospheric flux (dashed line).

## Ambipolar Diffusion Heating

Considering a steady flow accelerating in an inertial frame, the equation of motion can be written as

$$\rho_n \mathbf{a}_n = \rho_n \mathbf{g} + \mathbf{f}_d \quad (\text{B.1})$$

for the neutral species  $n$ , and

$$\rho_i \mathbf{a}_i = \rho_i \mathbf{g} - \mathbf{f}_d + \mathbf{f}_L \quad (\text{B.2})$$

for the ion species,  $i$ . The flow acceleration is defined as  $\mathbf{a} \equiv (\mathbf{v} \cdot \nabla) \mathbf{v}$  and the gravitational acceleration is  $\mathbf{g} \equiv \nabla(GM_\star/r)$ . The volumetric drag force of the ions on the neutrals is defined as

$$\mathbf{f}_d = \gamma \rho_n \rho_i (\mathbf{v}_i - \mathbf{v}_n) \quad (\text{B.3})$$

and  $\mathbf{f}_L$  is the volumetric Lorentz force. The equation of motion for the combined ion-neutral fluid is found by addition of Equations [B.1](#) and [B.2](#)

$$\rho \mathbf{a} = \rho \mathbf{g} + \mathbf{f}_L \quad (\text{B.4})$$

---

where  $\rho \equiv \rho_n + \rho_i$  is the mass density without the electrons and  $\mathbf{a} \equiv (\rho_n \mathbf{a}_n + \rho_i \mathbf{a}_i) / \rho$  is the total acceleration.

The gravitational acceleration term can then be eliminated from Equations B.1 and B.2 to give

$$\mathbf{a}_n - \mathbf{a}_i = \left( \frac{1}{\rho_n} + \frac{1}{\rho_i} \right) \mathbf{f}_d - \frac{1}{\rho_i} \mathbf{f}_L. \quad (\text{B.5})$$

Assuming then that the acceleration of the neutrals and ions are the same we get

$$\mathbf{f}_d = \left( \frac{\rho_n}{\rho_n + \rho_i} \right) \mathbf{f}_L. \quad (\text{B.6})$$

This equation tells us that for a lightly ionized outflow the drag force is almost equal to the Lorentz force. We can now obtain an expression for the slip velocity,  $\mathbf{w}$ , by subbing this equation into Equation B.3

$$\mathbf{w} = \mathbf{v}_i - \mathbf{v}_n = \frac{\mathbf{f}_L}{\gamma \rho_i (\rho_n + \rho_i)}. \quad (\text{B.7})$$

The slip velocity becomes large when the ion density becomes small, but does not become large when the neutral density becomes small because the large density of ions drag the few neutrals that are present along with the rest of the mostly ionized plasma. The heating rate per unit volume due to ambipolar diffusion heating is

$$\Gamma = \mathbf{f}_d \cdot \mathbf{w} \quad (\text{B.8})$$

and substitution of Equations B.6 and B.7 gives

$$\Gamma = \frac{\rho_n |\mathbf{f}_L|^2}{\gamma \rho_i (\rho_n + \rho_i)^2}, \quad (\text{B.9})$$

and so for a completely ionized plasma,  $\Gamma = 0$ .

In order to calculate the ambipolar diffusion heating, we need to find a value for the ion-neutral momentum transfer coefficient,  $\gamma$  (in units  $\text{cm}^3 \text{s}^{-1} \text{g}^{-1}$ ) which depends on the collisional coefficient rates, cross sections, slip speed, and gas

---

composition. [Shang \*et al.\* \(2002\)](#) give the following expression

$$\gamma = \frac{2.13 \times 10^{14}}{1 - 0.714x_e} \left( \left[ 3.23 + 41.0T_4^{0.5} \times \left( 1 + 1.338 \times 10^{-3} \frac{w_5^2}{T_4} \right)^{0.5} \right] x_{HI} + 0.243 \right) \quad (\text{B.10})$$

where  $T_4$  is the temperature in units of  $10^4$  K,  $w_5$  is the slip speed in units of  $\text{km s}^{-1}$ . We have assumed no molecular hydrogen to be present and the fractional abundance of He,  $x_{He} = 0.1$ . Subbing Equation B.7 into Equation B.10 gives a quartic equation for  $\gamma$ , i.e.,

$$\gamma^4 - (2AE + 2ABx_{HI})\gamma^3 + (A^2E^2 + 2A^2BE x_{HI} + A^2B^2x_{HI}^2 - A^2C^2x_{HI}^2)\gamma^2 - GA^2C^2x_{HI}^2 = 0$$

where

$A = \frac{2.13 \times 10^{14}}{1 - 0.714x_e}$ ,  $B = 3.23$ ,  $C = 41.0T_4^{0.5}$ ,  $D = \frac{1.338 \times 10^{-3}}{T_4}$ ,  $E = 0.243$ ,  $F = \frac{\mathbf{f}_L}{\rho_i(\rho_n + \rho_i)}$ , and  $G = \frac{DF^2}{1 \times 10^{10}}$ . Finally the radial and azimuthal Lorentz forces and thus the corresponding volumetric ambipolar heating rates can be calculated by using the following expressions for the flow and gravitational accelerations:

$$\mathbf{a} = v \frac{dv}{dr} \mathbf{r} + \frac{v}{r} \frac{dv}{d\theta} \boldsymbol{\theta} \quad (\text{B.11})$$

and

$$\mathbf{g} = -\frac{GM_\star}{r^2} \mathbf{r} + \frac{1}{r} \frac{d}{d\theta} \left( \frac{GM_\star}{r} \right) \boldsymbol{\theta}. \quad (\text{B.12})$$
